Irrigation and the Spatial Pattern of Local Economic Development in India^{*}

David Blakeslee[†] Aaditya Dar[‡] Ram Fishman[§] Samreen Malik[¶] Heitor Pelegrina[∥] Karan Singh^{**} August 2021

Abstract

We study the impacts of 1,500 large-scale irrigation projects that have affected more than 250,000 villages in India. To identify treatment effects, we use high-resolution spatial data, and exploit discontinuities in program inclusion arising at project boundaries. Irrigation increases agricultural output and population density in rural villages. However, in and near towns, it causes a decline in indicators of development including population density, night-light density, built-up area, and firm employment, reallocating factors of production away from non-agricultural activities. The results are consistent with a model in which permanent agricultural productivity gains slow the process of structural transformation.

1 Introduction

Policy makers in developing countries have long emphasized improvements in agricultural productivity as a central strategy for promoting rural development. Ultimately, however, economic development hinges upon firm creation and shifting employment from the agricultural to the manufacturing and service sectors, a process often linked to urbanization and migration (Johnston and Mellor, 1961; Lewis, 1954; Gollin et al., 2002; Rostow, 1960; Kuznets, 1961; Studwell, 2013). It is, therefore, crucial to understand how gains in agricultural productivity impact nonagricultural development.

This paper studies the effects of permanent agricultural productivity shocks on local economic development in India. Since 1950, the Indian government has extended irrigation to close to 250,000 villages through the construction of large-scale dams and networks of canals that distribute river water to downstream villages. We provide evidence that these irrigation projects had a positive impact on the agricultural productivity of rural villages by allowing them to expand crop production to seasons when it had previously been nonviable. However, we also show that the process of urbanization and the reallocation of labor to non-agricultural firm employment has slowed down within project areas.

Since the seminal work of Duflo and Pande (2007), a handful of papers have studied the impacts of surface irrigation projects on downstream areas, generally relying on exogenous variation in the geographical determinants of dam location for causal identification. These studies have documented important effects of irrigation on agricultural output, income volatility, and poverty rates (Hansen et al., 2011; Strobl and Strobl, 2011; Blanc and Strobl, 2014; Olmstead and Sigman, 2015; Jones et al., 2019; Zaveri et al., 2020).¹ However, less is known about the effects of irrigation on non-agricultural economic activity, which is the primary focus of our paper (see Dillon and Fishman, 2019 for a review).

Our analysis uses fine spatial data on more than 1,500 major surface irrigation projects in In-

¹Additional papers, including Hornbeck and Keskin (2014, 2015); Sekhri (2014); Fishman et al. (2013); Blakeslee et al. (2020); Ryan and Sudarshan (2020), have studied the impacts of decentralized groundwater irrigation on similar outcomes.

dia, which we merge with administrative village-level agricultural, demographic, and economic data, as well as remotely sensed land-use data. The boundaries of the areas served by these irrigation projects (also called "command areas") are primarily determined by engineering considerations related to topography (see Section 4 for details). We exploit the discontinuity in program inclusion arising at the boundary of command areas, comparing villages proximate to one another but on opposite sides of the boundary, while controlling for geographic features and imposing sampling restrictions to ensure comparability. This approach differs from much of the existing literature, which generally compares larger areas downstream from a dam to areas that are not.

The high resolution of our data allows us to provide novel insights on the impacts of irrigation on the spatial patterns of economic activity. In India, village population density and nonagricultural economic activity decline rapidly with distance from rural towns. Our analysis shows that the impacts of irrigation display remarkable variation across this distance gradient. Far from towns, where nearly all labor is engaged in farming, we find no significant effect of irrigation on village labor force composition and a modest increase in small firm employment. In stark contrast, in towns and nearby villages, irrigation causes a substantial increase in the share of agricultural workers and a large decrease in employment in firms, especially large ones. Similarly, most villages experience an increase in population density, built-up area, and nightlight density while towns experience a decrease. Proxy measures of per-capita wealth are also higher in irrigated villages, while in towns there is generally no improvement.

To guide the interpretation of our empirical results, we formulate a parsimonious spatial economy model in which non-agricultural activities are subject to dynamic external economies of scale, as in Matsuyama (1992). In our model, a positive agricultural productivity shock on urbanizing regions tends to slow this process, reducing non-agricultural employment, productivity growth, and the inflow of workers. In more remote agricultural villages, the same shock further deepens a region's specialization in agriculture and reduces the outflow of workers.

Our paper joins a growing literature on the causal impact of different forms of agricultural productivity gains on structural transformation. McArthur and McCord (2017) and Gollin et al.

(2018) utilize exogenous cross-country variation in the accessibility of key inputs to show that agricultural productivity gains accelerate structural transformation. Other papers use withincountry variation to study the impacts of increases in agricultural productivity. Bustos et al. (2016, 2020), for example, find that Brazilian municipalities with better agro-climatic conditions for the adoption of labor-augmenting technical change experienced higher rates of local structural transformation. Hornbeck and Keskin (2015) show that U.S. counties more likely to gain access to irrigation after World War II experienced long-run improvements in agricultural output, but did not experience long-term increases in non-agricultural activity. Foster and Rosenzweig (2004) show that high rates of crop yield growth in India were correlated with lower industrial growth across a nationally representative sample of villages. Relatedly, several papers study how climatic variation affects urbanization and labor allocation in Sub-Saharan Africa and India, presumably through its effect on agricultural productivity (Henderson et al., 2017; Emerick, 2018; Krishnaswamy, 2019; Colmer, 2021).²

We contribute to this literature by estimating the impact of permanent gains in agricultural productivity on long-term, local indicators of economic development in a major developing country. Our data allow us to examine the spatial patterns of these impacts at a finer resolution than previous papers, which tend to study outcomes at higher levels of administrative aggregation that generally include both urban locations and their rural hinterlands. Such analyses have provided extremely important insights about more aggregate effects, but do not determine how these effects are distributed spatially, or how this depends on baseline levels of urbanization. As demonstrated in this paper, agricultural productivity gains have substantial impacts on the patterns of labor allocation and firm activity across proximate rural and urban areas. It is important to note, however, that our methodology is less suited to identify the aggregate impacts of increases in agricultural productivity. We return to this question in the conclusion, and use back-of-the-envelope calculations to estimate aggregate effects. We also note concurrent and independent work by Asher et al. (2021) conducts a similar analysis and finds consistent results.³

²See Barrett et al. (2017) for a review of studies in Africa.

³The two groups have been developing their research independently and have become aware of each other's work

This paper also speaks to research on economic geography. Several papers have studied different drivers of the spatial distribution of economic activity in individual countries (e.g., Michaels et al., 2012; Bleakley and Lin, 2012; Allen and Donaldson, 2018; Davis and Weinstein, 2002). Most of this research has focused on developed countries. We contribute to this literature by providing evidence on the impact of local agricultural productivity shocks on the location of production in India. In addition, by showing reduced-form evidence on how agricultural productivity shocks interact with the spatial distribution of economic activity, we complement recent papers studying interactions between structural transformation and economic geography, such as Gollin and Rogerson (2014), Nagy (2020), Eckert et al. (2018), Fajgelbaum and Redding (2018), and Henderson et al. (2018).

Lastly, our results relate to a rich literature studying the effects of agricultural productivity gains on various outcomes, including several papers on the "green revolution" (Christiaensen and Martin, 2018; Gollin et al., 2018; Bharadwaj et al., 2020; von der Goltz et al., 2020) and studies on irrigation (Hornbeck and Keskin, 2014; Dar, 2019; Blakeslee et al., 2020).

2 A Simple Spatial Economy Model with Structural Transformation

This section develops a parsimonious spatial economy model, in which productivity in urban activities are subject to dynamic external economies of scale as in Matsuyama (1992). Our model predicts theoretically ambiguous effects of an agricultural productivity shock on non-agricultural activities, depending on the distance of affected regions to population hubs. We briefly explain the model here, relegating details to Appendix A1.

Setup. Consider a small open economy with two regions, called Town (T) and Village (V), and two sectors, agriculture (A) and manufacturing (M). The economy operates over discrete time.

in March 2021. Asher et al. (2021) also implement a regression discontinuity design but using elevation relative to a canal as the running variable.

Relative to Village, Town is situated in a privileged geographic area, near a major trade route or a river, such that trade between Village and the rest of the world (ROW) has to pass through Town. To take goods from Village to Town, there is an iceberg trade cost of τ . This economy has a population N that can move between regions and sectors. Each region has a land endowment of L. Markets are perfectly competitive.⁴

Technologies are given by

$$q_{ikt} = A_{ikt} \left(L_{ikt} \right)^{\alpha_k} \left(N_{ikt} \right)^{1 - \alpha_k}$$

where *i* indexes a region, *k* a sector, and *t* a time. A_{ikt} is the productivity, L_{ikt} the employment of land, N_{ikt} the total labor employment, and α_k the cost share of land. Agriculture is landintensive ($\alpha_A > \alpha_M$). Agricultural productivity is fixed ($A_{iAt} = A_{iA}$). As in Matsuyama (1992), manufacturing productivity is subject to knowledge accumulation:

$$A_{iMt+1} = A_{iMt} + \gamma n_{iMt}$$

where $\gamma > 0$ is an externality parameter and n_{iMt} is the share of workers in manufacturing $(n_{iMt} \equiv N_{iMt}/N_{it})$, where N_{it} is the total population in *i*). We assume $A_{TA} = A_{VA}$ and $A_{TM0} > A_{VM0}$, where t = 0 is the initial period.

In every region, land consists of a continuum of plots and landowners assign plots to sectors. Each plot requires a conversion cost of ϵ_k to be employed in sector k, incurred by the landowner. Similar to Sotelo (2020), this conversion cost is heterogeneous across plots and drawn from a Fréchet distribution, $F(\epsilon) = 1 - exp(-\epsilon^{-\theta})$, where θ controls the variance of conversion costs. With this formulation, as they maximize profits, landowners assign a share $\lambda_{ikt} = r_{ik}^{\theta} / \sum_{k'} r_{ik'}^{\theta}$ of plots to sector k, where r_{ik} is the rent of converted land.⁵

⁴For simplicity, workers are perfectly mobile. We could introduce migration costs in the model, consistent with the literature on migration in India (Munshi and Rosenzweig, 2016), but that would not change the essence of our results.

⁵Land heterogeneity avoids non-degenerate equilibria in which a region fully specializes in one of the sectors. We notice that, in contrast to Sotelo (2020), who model plots of land as heterogeneous in terms of their productivity,

Lastly, consumers have Cobb-Douglas preferences. The expenditure share of agriculture and manufacturing are, respectively, μ_A and μ_M .

Dynamics and the Spatial Distribution of the Economy. The evolution of prices in Town is exogenous, tracking prices in the ROW.⁶ In Village, prices are determined by non-arbitrage conditions across space. Because Town is closer to the ROW, it tends to attract workers and have a larger population density. As such, land to wage ratios in Town are higher, inducing specialization of Town in manufacturing and specialization of Village in agriculture. In any given period, both population density and the share of manufacturing workers are larger in Town.

Over time, productivity growth in Town is larger than in Village because of knowledge accumulation in manufacturing. As a result, Town increasingly attracts workers and specializes in manufacturing. In Village, population density falls over time, and the region increasingly specializes in agriculture.

Agricultural Productivity Shocks. Consider now a shock at t = 0 that increases agricultural productivity permanently, either in Town or in Village. In both regions, this shock reduces permanently the share of workers and land in manufacturing relative to a scenario without the shock. In Town, this reduction slows down the productivity growth in manufacturing, reducing the inflow of workers over time. In Village, this shock also reduces the productivity growth in manufacturing, but it tends to prevent the outflow of workers by making the agricultural sector more attractive, increasing population in Village relative to a scenario without the shock. (Appendix Figure A1 illustrates these effects using numerical simulations of the model.)

In summary, an agricultural productivity shock increases the share of workers in agriculture, both in Village and in Town, which is consistent with empirical findings in Foster and Rosenzweig (2004). Importantly, our model also generates ambiguous predictions about the impact of a productivity shock on population growth, depending on the spatial distribution of economic

we assume that plots of land, once converted to a sector, are homogeneous. Our approach simplifies the solution of the model while retaining our goal of avoiding full sectoral specialization.

⁶Appendix A1 characterizes prices in the ROW.

activity, which we inspect empirically in Section 5.

3 Data

We make use of a variety of data sources available at high spatial resolution. The key outcome variables come from: (a) demographic and economic censuses, available at the village and town level; and (b) remotely sensed data on cropping patterns, land use, and nighttime lights. The latter are merged to georeferenced villages and towns, along with GIS data on canal command areas and key geographic factors. Additional detail is provided in Appendix A2.

Demographic and economic census. The demographic census of India is conducted every ten years. It includes data on demographics, economic activity, educational attainment, land use patterns, and household amenities and assets for the entire country, aggregated at the village and town level. We make use of the following outcomes from the 2011 census: irrigated area, canal-irrigated area, population density (per sq km), labor force participation, employment in agriculture (both own-farm cultivators and agricultural laborers), and ownership of assets and household amenities. We also use data from the sixth edition (2012-13) of the economic census, which provides firm-level data on employment for all enterprises in the country, including both the sector and number of workers within each firm. It is important to note that, while the demographic census reports the numbers of workers and farmers residing in the village, the economic census reports the number of employees of firms which are located in the village/town, whether they reside in it or not.

Remotely Sensed Data. We use three sources of satellite data with information on agricultural outcomes. First, we utilize data on dry season cropping from MODIS Enhanced Vegetation Index (EVI) to measure cropped area at small-scale farming environment (Jain et al., 2017). The data are available at a 1×1 sq. km resolution, and aggregated using village and town polygons. Second, we use land use and land cover classification (250K) data from *Bhuvan*, the Indian Space Research Or-

ganisation's (ISRO) online portal.⁷ The data are made available by the Natural Resources Census programme at National Remote Sensing Centre (NRSC), which uses remote sensing to estimate land use in different categories, including: season-wise cropping, double or triple-cropping, fallow area, built-up area, forest area, wasteland, and water bodies. These data are used to estimate net sown area in the country, as they have a high accuracy (Agency, 2007). Third, as a proxy for economic growth and urbanization, we use nighttime lights data from NOAA's National Geophysical Data Center's Defense Meteorological Satellite Program (Henderson et al., 2012).

Spatially Linked Data. Using village and towns polygons, we combine the data sets described above to construct a high resolution spatial data set on economic activity in the country. We also merge GIS data on canals, command areas, aquifers, and rivers from the India Water Resources Information System (WRIS).⁸ Attribute data on canals is completed using Central Water Commissions' Management Information System of Water Resources Projects and India WRIS Wiki.⁹ Finally, we calculate distances from village centroids to command area boundaries, and complement the data with detailed information on geographical features including climate, altitude, slope and a land ruggedness index formulated by Riley et al. (1999), and used by Nunn and Puga (2012) and Michaels and Rauch (2017).

Summary Statistics. Appendix Table A2 gives key details on the sample size and descriptive statistics. The sample cover approximately 1,500 irrigation projects; and includes approximately 74,000 villages and 900 towns within program areas, and similar numbers in nearby control areas. To put these numbers in perspective, there are approximately 650,000 villages and 7,700 towns in India. Therefore, our sample of treated villages and towns accounts for approximately 11-12 percent of all villages and towns in India.¹⁰

⁷http://bhuvan.nrsc.gov.in/gis/thematic/index.php

⁸Data downloaded from http://59.179.19.250/ during Nov 2019–Apr 2020. The link, however, is now inaccessible.
⁹https://indiawris.gov.in/wiki/doku.php

¹⁰Out of the 567,125 villages for which data is available, 16 percent do not get any irrigation. Overall, the average percentage of cultivated land in Indian villages that is irrigated from any source is 52 percent and the average cultivated area irrigated by canals is 12 percent. After tubewells, canal irrigation is the second most popular means of irrigation and close to 144,000 villages (24 percent of all villages in the country) report receiving water from canals.

Descriptive statistics for villages are given in column (1), and columns (2)–(4) report the differences between towns and villages, with column (3) including command area fixed effects, and column (4) additionally restricting the sample to towns smaller than 30 sq kms. As is apparent, towns are systematically different than villages, having larger populations, smaller agricultural sectors, more large firms (per capita), and greater household asset holdings. These significant differences across villages and towns also motivate the spatial analysis and the empirical strategy we describe next.

4 Empirical Strategy

Our empirical strategy exploits the discontinuity in program inclusion arising at the boundary of command areas, comparing villages (towns) proximate to one another on opposite sides of the boundary. Command areas are defined as the total areas to which an irrigation project can deliver water through a network of canals. The extent of the command area is determined by the volume of water in storage (mostly in a dammed reservoir, but occasionally through direct diversion of an un-dammed river) and the topography of the terrain. Since water is distributed through gravity, elevation plays a key role in determining the boundary. In one of the most common engineering designs, the main canals begin at the dam and follow a roughly constant elevation contour, from which secondary canals deliver water to lower elevations. The command area boundary is thus formed by these main canals. In another common design, the main canals follow ridge lines and secondary canals distribute water to both sides of the ridge. The boundary of the command area is then defined by lowest elevation lines on both sides of the ridge and the terminus of the main canals. Using elevation data, we confirm that the the command area boundaries are essentially flat, with average slopes on the order of a 20 cm decline per 100 meters distance.

Notes: The empirical strategy compares villages on either side of the command area border (shaded light grey) in a 10 km buffer (denoted by the dotted black line). In order to compare nearby villages, 5 km boundary segment fixed effects are used, which are calculated by splitting the border into smaller parts. (Boundary segments not shown for the sake of simplicity.) Furthermore, the estimating sample is restricted to parts of the border which have a slope less than 1.5 degrees on the outside of the border. (This sample restriction gives us a balanced sample on key geographic variables. See Figure 2.) This map also illustrates the two types of estimation samples that are used in the study: the main results use the entire canal command area boundary, with the caveats mentioned above. A second estimation sample, used in robustness checks, relies only on the part of the command area boundary that is contiguous with the canal. In this example, only villages on either side of the command area border (black solid line) which overlaps with the canal (red solid line) will be used.

Our analysis encompasses approximately 1,500 irrigation projects (command areas), for which we have high resolution data on the precise boundaries of command areas, as well as canals and all relevant geographic features. To improve the comparability of the control and treatment groups, we restrict the sample to villages and towns whose centroids are no farther than 10 kms from the boundary (see Figure 1), but our results are not affected by the choice of a narrower or wider bandwidth.¹¹ To sharpen the comparison even further, we partition the boundaries of command areas into 5 km segments (of which there are, on average, 16 per command area), and compare only villages on opposite sides of the same boundary segment.

Formally, our main estimation takes the form:

$$y_{ipdb} = \alpha + \beta C_i + \mathbf{X}_i \Gamma + \nu_d + \mu_b + \varepsilon_i, \tag{1}$$

Agricultural and non-agricultural outcomes are denoted by y_{ipdb} , where *i* is an index for location (village or town) in a 10 km buffer around irrigation project *p* in district *d* and *b* is an index for 5 km command area boundary segments. The key explanatory variable of interest, C_i , is a binary variable indicating whether the centroid of the location lies within a command area or not, and the coefficient of interest is β which is the impact of irrigation on agricultural productivity and local economic development. Our preferred specification includes district fixed effects, ν_d , and μ_b which are the 5 km boundary segment fixed effects, assigned according to the boundary segment to which a centroid of a given location is closest.¹² We also control for a vector of village geographic characteristics, X_i , which includes altitude, ruggedness, distance to major river, type of groundwater aquifer underlying the village, and the (log) area of the village. We discuss these in detail below. To account for spatial correlation, error terms are clustered at the command area level.

We estimate treatment effects for villages and towns separately because of their starkly different economic characteristics (see Appendix Table A2 and Appendix Figure A2). Identical specifications with the same 10 km bandwidth are used for both to facilitate comparability. It is important to note that, while the possibility of endogenous town formation in response to irrigation

¹¹Given that there is no well accepted method to select bandwidth in a multi-dimensional regression discontinuity (Dell and Olken, 2020), our chosen bandwidth is one of the most conservative in the literature in comparable contexts. Prior border design studies set in a developing country typically have a bandwidth between 25 km and 200 km (such as, Dell, 2010; Michalopoulos and Papaioannou, 2013; Dell and Querubin, 2018).

¹²In the Appendix, we include additional analysis which replaces the boundary segment fixed effects with project fixed effects while maintaining district fixed effects.

could confound the estimation for villages and towns, we find no evidence that the *existence* of towns is impacted by the command area (Appendix Table A1).

We subject our results to several robustness tests. First, we consider alternative choices of bandwidths and document that the results in both villages and towns are robust to varying the bandwidth between 2 km and 30 km. Second, we control for (a linear spline in) the distance from the village to the command area boundary (omitting villages that are partially inside the command area), as is customary in spatial discontinuity designs carried out over larger spatial scales. It is important to note that the narrow extent of the spatial sample we use for our estimation makes such controls less crucial, while the possibility of spillovers undermines one of the key requirements of this research design. Third, we use Conley standard errors that account for spatial correlation across villages at distances of up to 300 kms. Fourth, we winsorize the outcome variables at the 5th and 95th percentiles.

Our approach is similar in spirit to spatial regression discontinuity designs that have been employed in a number of papers (Dell, 2010; Sukhtankar, 2016; Dell and Querubin, 2018; Dell and Olken, 2020; Ahlfeldt et al., 2015; Egger and Lassmann, 2015; Gonzalez, 2021; Smith, 2019). The identifying assumption in such designs is that other than the treatment, all factors that can potentially affect the outcomes of interest vary smoothly at the boundary. In our case, this assumption is motivated by the plausible argument that prior to the construction of an irrigation project, there would be little reason to expect the command area boundary, determined as it is through a highly specific function of topography and the volume of the reservoir, to coincide with substantial breaks in other geographical or socio-economic variables. A similar argument is made by Jones et al. (2019) and Blakeslee et al. (2019), who evaluate specific surface irrigation projects in Rwanda and India, respectively.

We consider two principal threats to the identifying assumption. The first relates to potential differences in geography across the command area boundary, which may arise if engineering considerations result in command area boundaries that coincide with breaks in certain geographical features of the terrain. For example, it may be deemed optimal to place the boundary along the base of a hill or the border of a forested area.

2.3: Distance to River

2.4: Aquifer

Notes: The above figure compares key geographic features in villages inside the command area (to the left of 0) with those just outside (to the right of 0). Distance to the command area (in km) is on the x-axis. The solid line represents results from a regression of pre-determined, geographic characteristics on canal command area treatment dummy, binned distances, controls and 5 km boundary segment fixed effects. Standard errors are clustered at the project code level. The dotted lines illustrate the 95 percent confidence intervals. The black lines refers to the full sample while the blue lines refers to the restricted/trimmed sample (see definitions in text). Figure 2.1 depicts altitude (in meters), Figure 2.2 depicts the terrain ruggedness index derived from USGS digital elevation models, Figure 2.3 depicts distance to river (in kms), and Figure 2.4 depicts whether a village lies on top of an alluvium/water-deposited aquifer.

Figure 2 displays plots (black lines) of key geographic variables (altitude, type of aquifer, ruggedness, and distance to river) against the distance between a village and the nearest command area boundary. The plots do not indicate discontinuous jumps, but do suggest trend breaks in elevation and ruggedness. However, when we limit the sample to villages lying in the vicinity

of boundary segments for which the average slope on both sides is very moderate (less than 1.5 degrees), no such trend breaks are visible (blue lines in Figure 2). We therefore use this sampling restriction in our analysis.¹³ Appendix Figure A3 displays the geographic coverage of the trimmed sample.

Because the geographic variables generally trend monotonically with elevation, and because the latter is one of the key determinants of inclusion in the program area, small differences in geographic characteristics will necessarily be present across the boundary even under our conservative sampling restriction. For this reason, we control for all of these variables in our regressions. In practice, however, the magnitude of the differences is small and of negligible agricultural significance (Appendix Table A3).¹⁴

The second threat to identification is posed by the possibility that non-engineering considerations may influence the boundaries of the irrigation project, such as the desire to include politically favored villages in the command areas. If differences in outcomes across the boundary were driven by unobservable factors associated with such favored villages, one would expect treatment effects to be particularly large at the boundary, and to decline at greater distances. As we show below, we find no evidence for such patterns in plots of outcomes against distance to the boundary, nor do we find materially different treatment effects when omitting villages just inside the command area from our regressions.

Several additional tests of the identification assumption are reported in the results section. This includes a placebo analysis using only those projects that have been initiated after the year 1991, and testing whether treatment effects are apparent for 1991 outcomes (using the same regression specification). In addition, we conduct an analysis limiting the sample to only those boundary segments that are demarcated by irrigation canals. Because such canals follow approximately fixed elevation contours, and the command area consists exactly of the area on their

¹³Canal boundaries where the canal is within 500m of a river are also excluded.

¹⁴For example, there is a 5 meter elevation difference between control and treatment villages (10 km bands), in comparison to a control mean of 200 meter, amounting to 0.01 standard deviations. Ruggedness differs by only 2 points on the Riley index, compared to a control mean of 39, where any value of this index between 0 and 80 is considered level terrain.

downhill side, treatment status for villages along these segments is determined by transparent and fundamental engineering considerations.

5 Results

Agricultural Outcomes. In our first set of results, we present the impact of being included in the command area on several agricultural outcomes, including: the percentage of agriculture land that is irrigated; the share of land that is used for multiple-season cropping; and the extent of dry season cultivation (EVI).

We illustrate the results graphically in Figure 3.1–3.3, which plots these outcomes (or rather, residuals from regressions of these outcomes on all control variables in specification 1) against distance bins from the boundary, labelling distance as negative within the command area and positive outside of it.¹⁵ Results for regressions without controls are depicted in Appendix Figure A5.1–A5.3. All three outcomes display clear discontinuities at the boundary.

We report regression estimates using several alternative agricultural outcomes in Appendix Tables A4 and A5. Within command areas, the share of agricultural land that is irrigated by canals increases by around 8.4 percentage-points (p.p.), representing a more than 150% increase over the control mean (5.1 p.p.).¹⁶ These effects are large in proportional terms but modest in magnitude, consistent with the generally poor assessment voiced by observers of the success of these projects in increasing irrigated area. Canals are one of several potential sources of irrigation raising the possibility that substitution to other sources may attenuate the net effect on irrigation. However, the overall share of irrigated agricultural area increases by 5.6 p.p., representing a 13% increase over the mean value outside the command area. We also estimate a 7.0 p.p. increase in the remotely sensed share of cultivated village area, a 7.3 p.p. increase in the share of land with multi-season cropping, and an increase in dry season vegetation indices (EVI) (Appendix Table A5).

¹⁵The plot excludes villages which overlap the boundary and for which treatment status is poorly measured. These villages are typically located within 2-3 kms of the boundary.

¹⁶Census data on irrigated and cultivated areas are only reported for villages.

Figure 3: Agriculture and Development

3.5: Log Light Density

3.6: Log Firm Employment

Notes: The above figure compares key agricultural and development outcomes in villages inside the command area (to the left of 0) with those just outside (to the right of 0). Distance to the command area (in km) is on the x-axis. The solid line represents results from a regression of outcomes on canal command area treatment dummy, binned distances, controls and 5 km boundary segment fixed effects. Standard errors are clustered at the project code level. The dotted lines represent 95% confidence intervals. Figure 3.1 depicts area under irrigation as percent of cultivable land; Figure 3.2 depicts land area that is cropped twice or thrice as percentage of agricultural area; and Figure 3.3 depicts dry season vegetation indices as percentage of total village area. Figure 3.5 depicts mean nighttime lights per sq km. Figure 3.6 depicts number of employees in firms across manufacturing, agriculture and services enterprises.

The effects in towns are somewhat larger, except for vegetation indices, which are smaller and imprecise. Though we lack data on agricultural yields at the required spatial resolution, the clear discontinuities in these outcomes at the boundary and the increase in the number of crops grown in a single year suggest a substantial increase in *annual* agricultural output per acre.

Urbanization and Development. We next turn to impacts on urbanization and development, which we measure through the distribution of population, built-up area, and nightlight density. Similar to the illustration for agriculture outcomes, we present our results for urbanization and development for villages graphically in Figure 3.4–3.6. Results for regressions without controls are depicted in Appendix Figure A5.4–A5.6. All three outcomes display clear discontinuities at the boundary.

In Figure 4.1 and Appendix Table A6 we report estimates of the impact of canal irrigation on these outcomes (measured in logs) for villages and towns separately. For villages, we estimate a 6.1% increase in village population density, a 6.5% increase in light density, and a 3.5% increase in the built-up area. For towns, however, we observe opposite effects, with a 30.8% decline in population density, a 26.1% decline in light density¹⁷, and a 26.8% decline in built-up area. These opposing effects for villages and towns are consistent with the ambiguous impact of agricultural productivity shocks highlighted in our model. To appreciate the magnitude of these effects, it is worth bench-marking them against the modest (13%) effect on irrigated area, implying irrigation elasticities for these outcomes of substantial magnitudes.

Labor Force Composition. In Figure 4.2 and Appendix Table A7, we document the impact of canal irrigation on labor force participation and composition using demographic census data. We do not find significant effects in villages; but, in towns, we estimate an increase of 3.3 p.p. (24%) in the share of workers engaged in farming, driven by increases in both land-owning cultivators and landless agricultural laborers.

¹⁷This effect is statistically insignificant when we include district fixed effects instead of 5-km boundary fixed effects.

Figure 4: Labor Force Participation, Firm Activity and Assets

4.3: Employment in Firms

4.4: Assets

Notes: The above figure plots β from equation 1 for key non-agricultural outcomes in villages and towns. Figure 4.2 depicts the impact on labor force participation (Census of India 2011): employed refers to workers as % of population; farmers refers to sum of cultivators and agricultural laborers as a % of all workers; cultivators refers to those directly involved in farming or supervision of farming, and unlike agricultural labors they work on their own farm. Figure 4.3 depicts ln(employment) in firms by sector and firm size (Economic Census 2012-13). All refers to sum of workers employed in manufacturing, agriculture and services enterprises. Sectors are classified using Ministry of Statistics and Programme Implementation's National Industrial Classification. Firm size is measured using number of workers: employees, ≥ 100 , 50-99, 10-49 and < 10refers to firms with more than 100 workers, between 50 and 99 workers, between 10-49 workers and less than 10 workers respectively. Figure 4.4 depicts assets and amenities as % of households in villages/towns (Census of India 2011). Variables are self-explanatory.

Firm Activity. We also examine impacts on firm activity, which we measure through the (log) employment in firms which are located in a given village or town, by sector and size. Results are depicted in Figure 4.3 and reported in Appendix Table A8 in greater detail. Employment in firms increases by 5.8% in villages, with effects evident for manufacturing (4.6%) and service firms

(7.2%). The effects are mostly driven by small firms (less than 10 workers). For towns, in contrast, we find large, negative effects, with firm employment being 58.3% lower in command areas, which is driven by declines in both manufacturing (73.3%) and services (47.5%). Importantly, there are particularly large declines in all sizes of firms, where employment is more than 50% lower.

Assets. Figure 4.4 and Appendix Table A9 report estimated impacts of canal irrigation on various measures of asset holding and home amenities. In villages, we see substantial increases in the fraction of households owning most types of assets and the quality of housing facilities. In contrast, we find no evidence for corresponding effects on asset holdings in towns.

Additional Identification Tests and Robustness. We perform several additional estimations that provide indirect tests of our empirical approach. First, in Appendix Table A10 and Appendix Figure A4 we repeat the village estimation for key outcomes while restricting the sample to command area boundaries which are formed by irrigation canals. The results remain similar.

Second, in Appendix Table A11, we conduct a placebo analysis which limits the sample to villages for which the nearest command area was initiated *after* 1991, and outcomes are measured through the 1991 demographic census, 1993 light density, and 1990 economic census firm employment. We find no statistically significant impacts on any of the key outcome variables, and the point estimates are an order of magnitude smaller than in our main analysis, providing added confidence in our approach.

Third, we estimate our main results by controlling for (a linear spline in) the distance from the village to the command area boundary (omitting villages that are partially inside the command area). Appendix Table A12, Panel A presents estimates for villages while Panel B reports estimates for towns. A comparison of these results with those from equation 1 show that adding distance to boundary controls are less crucial as both the point estimates and statistical significance are very similar to the main results.

Fourth, while we present our results using the 10-km bandwidths, in Appendix Figures A6 we also use alternative bandwidths ranging from 2km–30km. We show that the results are robust.

Fifth, we examine the possibility that the results are driven by the deliberate manipulation of the command area boundary to include certain favored villages. For this, we re-estimate impacts on key outcomes while removing the treated villages that are closest to the boundary (within 2 km). These are the villages which are the ones most likely to be driving manipulation of the boundary. Were the treatment effects in fact being driven by unobservable attributes of these influential villages, then we would expect the treatment effects to decline with the exclusion of these villages. Reassuringly, the results are essentially unchanged both in magnitude and significance (Appendix Table A13).

Lastly, we estimate our main results while removing villages which intersect the boundaries (Appendix Table A14, Panel A); with winsorized outcome variables at the 5th and 95th percentiles (Appendix Table A14, Panel B); and with Conley standard errors that account for potential spatial correlation in errors across villages that are up to 300 km apart (Appendix Table A14, Panel C). The results are not materially affected.

Heterogeneous Treatment Effects by Proximity to Towns. To better understand the interaction between agricultural productivity shocks and the spatial distribution of economic activity, we next explore whether treatment effects for villages vary by distance to towns. This analysis is motivated by Appendix Figure A2, which depicts a strong relationship between distance to the nearest town and a variety of demographic and economic variables (with distance set at 0 for towns themselves).

Appendix Table A18 reports similar regressions for household assets and home amenities. Results indicate that villages close to towns are somewhat worse off on a per-capita basis in command areas.

Figure 5 plots the magnitude of treatment effects for villages at various distances from the nearest town. The effects of irrigation on village population and built-up areas are positive further from towns, but in their vicinity become negative: villages within 2 kms of a town experience an approximately 10% decline in population density (Figure 5.1) and built-up land (Figure 5.2).

Figure 5: Treatment Effect by Distance to Town

Notes: The above figure plots the coefficient on the interaction of the treatment dummy in villages with distance to towns for urbanization, agricultural and non-agricultural outcomes. Figure 5.1, Figure 5.2, 5.3 and Figure 5.4 depict heterogeneous effects for population, built-up area, farmers and employment in manufacturing firms. Definitions same as before.

We also find that increases in the share of farmers in the workforce documented for towns also occurs for villages in the vicinity of towns (Figures 5.3; and that the same is true of employment in manufacturing firms 5.4). Appendix Tables A15, A16, and A17 present corresponding estimates and robustness tests, using a (treatment-interacted) binary indicator for town-proximity which takes a value of 1 for villages within 4 kms of the nearest town.

6 Conclusion

Over much of the 20th century, the construction of large-scale surface irrigation infrastructure was one of the most capital-intensive investments by governments wishing to boost agricultural economies in low and middle income countries. This paper evaluates the impacts of such irrigation projects in India, one of the countries which has pursued this strategy most vigorously since its independence.

Surface irrigation projects have long been criticized for their inefficient performance. While confirming the relatively modest local impact of these projects on irrigation, we nonetheless find important impacts on broader patterns of economic development. We show that gains in agricultural productivity cause increases in rural populations and overall rural development, but simultaneously cause declines in urban population, light density, and firm activity. Two mechanisms are likely driving this result. First, increases in agricultural productivity may impede rural-to-urban migration by increasing incomes from agriculture. Second, the higher returns to agriculture may increase the cost of land, thereby lowering the profits of non-agricultural firms and reducing firm activity.

We also find that the impacts of irrigation are sharply mediated by the proximity of villages to rural towns. In more distant villages, irrigation increases population density, night light density, and built-area, while also modestly increasing per-capita wealth. However, for villages closer to towns, these effects generally have the opposite sign, and in fact more closely resemble the treatment effects for towns. In towns themselves, population, nightlight density, and firm activity are lower than in non-irrigated areas, and greater shares of the labor force are retained in agriculture. These effects are consistent with a simple spatial economy model in which permanent agricultural productivity gains slow the process of structural transformation.

The ability to simultaneously conduct our analysis at a fine (village-level) spatial resolution and on a country-level scale allows us to estimate local impacts of surface irrigation that are both well-identified and externally valid. It also provides us with a unique opportunity to examine how the impact of these projects on local structural transformation interact with the spatial distribution of economic activity. However, our research design is less well suited for estimating aggregate effects at larger regional scales, which is useful for (partially) accounting for general equilibrium effects. As an alternative, we conduct a back-of-the-envelope analysis using the estimated parameters and mean levels of the relevant variables (including village and town populations) in control areas. We find that there is: no net change in population; a 4.3% increase in agricultural workers; a 25% decline workers in employment in manufacturing firms; a 31% decline in employment at large firms (\geq 50 workers); and a 3% increase in light density.

Overall, we find that local agricultural productivity gains arising from irrigation expansion can bring substantial benefits to rural farmers, but that they can also hinder local structural transformation in urbanized areas. Further investigation into the welfare impacts of permanent gains in agricultural productivity is left for future work.

A1 Appendix: Theoretical Framework

This section characterizes the equilibrium of the model presented in the main body in detail. We start by solving the problem of landowners. We then show the evolution of prices in the rest of the world. Lastly, we present the equations that define the equilibrium in the domestic economy. To save on notation, we drop index of region and time in what follows, unless otherwise indicated.

Landowners. In each region, total land consists of a continuum of plots $\ell \in L$, where L is the total area of the region. There is a landowner in each region who chooses how to assign plots between agriculture and manufacturing. To be assigned to sector k, landowners have to incur a conversion cost of $e_k(\ell)$, proportional to land rents. The maximization problem of the landowner is thus

$$\max_{k} r_{k} e_{k}\left(\ell\right)$$
 .

We assume that conversion costs are drawn from a Fréchet, $F(\epsilon) = 1 - exp(-\epsilon^{-\theta})$. We can derive the share of land employed in activity k as follows

$$\begin{split} \lambda_{k} &= \int_{0}^{\infty} P\left(r_{k}e_{k} > r_{k-}e_{k-}\right) \exp\left(-e_{k}^{-\theta}\right) \theta e_{k}^{-\theta-1} de_{k} \\ &= \int_{0}^{\infty} P\left(e_{k}\frac{r_{k}}{r_{k-}} > e_{k-}\right) \exp\left(-e_{k}^{-\theta}\right) \theta e_{k}^{-\theta-1} de_{k} \\ &= \int_{0}^{\infty} \exp\left(-\left(e_{k}\frac{r_{k}}{r_{k-}}\right)^{-\theta}\right) \exp\left(-e_{k}^{-\theta}\right) \theta e_{k}^{-\theta-1} de_{k} \\ &= \int_{0}^{\infty} \exp\left(-e_{k}^{-\theta}\left(\frac{r_{k-}^{\theta} + r_{k}^{\theta}}{r_{k}^{\theta}}\right)\right) \theta e_{k}^{-\theta-1} de_{k} \\ &= \left(\frac{r_{k}^{\theta}}{r_{k-}^{\theta} + r_{k}^{\theta}}\right) \int_{0}^{\infty} \exp\left(-\left(\frac{r_{k-}^{\theta} + r_{k}^{\theta}}{r_{k}^{\theta}}\right) e_{k}^{-\theta}\right) \theta\left(\frac{r_{k-}^{\theta} + r_{k}^{\theta}}{r_{k}^{\theta}}\right) e_{k}^{-\theta-1} de_{k} \\ &= \left(\frac{r_{k}^{\theta}}{r_{k-}^{\theta} + r_{k}^{\theta}}\right) \end{split}$$

Market Equilibrium in the Foreign Economy. Since workers are freely mobile, marginal productivity must equalize between sectors

$$p_{A}A_{A}(1-\alpha_{A})(L_{A})^{\alpha_{A}}(N_{A})^{-\alpha_{A}} = A_{M}(1-\alpha_{M})(L_{M})^{\alpha_{M}}(N_{M})^{-\alpha_{M}}$$

Rearranging the equation gives

$$p_{A} = \frac{A_{M}}{A_{A}} \frac{(1 - \alpha_{M})}{(1 - \alpha_{A})} \frac{(L_{M}/N_{M})^{\alpha_{M}}}{(L_{A}/N_{A})^{\alpha_{A}}}$$

Let us now obtain L_M , L_A , N_A , and N_M as a function of the parameters. First, labor market clearing gives

$$N_k = N\mu_k.$$

For land employment, first use the following expressions coming from the FOC of firms

$$\frac{N_k}{L_k} = \frac{1 - \alpha_k}{\alpha_k} \frac{r_k}{w}.$$

The maximization problem of landowners gives

$$\frac{r_A}{r_M} = \left(\frac{L_A}{L_M}\right)^{\frac{1}{\theta}}.$$
(A1)

Combining the three expressions above, after some tedious algebra, we get

$$\frac{L_M}{L_A} = \left(\frac{\mu_M}{\mu_A} \frac{1 - \alpha_A}{\alpha_A} \frac{\alpha_M}{1 - \alpha_M}\right)^{\frac{\theta}{1 + \theta}}$$
(A2)

which together with $L = L_A + L_M$ characterizes the optimal allocation of land as an explicit function of parameters. Optimal labor and land allocation are therefore constant over time. Let L_A^* , L_M^* , N_A^* , N_M^* be the equilibrium values in Foreign. The price of agricultural produce at time t in the rest of the world, indexed by F, is

$$p_{FAt} = \frac{A_{FMt}}{A_{FAt}} \frac{(1 - \alpha_M)}{(1 - \alpha_A)} \frac{(L_M^*/N_M^*)^{\alpha_M}}{(L_A^*/N_A^*)^{\alpha_A}}.$$

Let n_{FM}^* be the optimal share of workers in manufacturing, the evolution of A_{FMt} is then $A_{FMt+1} - A_{FMt} = (n_{FM}^*)^{\gamma}.$

Market Equilibrium in the Domestic Economy. We now turn to the domestic economy. Sectoral prices in Town are the same as in the ROW. In Village, to define sectoral prices, we need to define its trade patterns. Given autarky price $p_{VA,t}^A$, Village is an exporter of agricultural goods if $p_{VA,t}^A \tau < p_{FA,t}$, in which case we have $p_{VA,t} = \tau p_{FA,t}$ and $p_{VM,t} = \frac{1}{\tau}$, an importer of agricultural goods if $p_{FA,t} \tau < p_{VA,t}^A$, in which case we have $p_{FA,t} = \frac{1}{\tau} p_{VA,t}$, and in autarky if $1/\tau < p_{VA,t}^A/p_{FA,t} < \tau$, in which case we have $p_{VA,t} = p_{VA,t}^A$.

Given sectoral prices, we now define the equations that characterize the equilibrium in terms of the price of factors of production (rents and wages) and the of workers and land between sectors and regions. First, marginal productivity of labor and land gives

$$r_{ik} = p_{ik} A_{ik} \alpha_k \left(\frac{N_{ik}}{L_{ik}}\right)^{1-\alpha_k} \tag{A3}$$

$$w_{i} = p_{ik}A_{ik}\left(1 - \alpha_{k}\right) \left(\frac{L_{ik}}{N_{ik}}\right)^{\alpha_{k}}$$
(A4)

Second, first order conditions of firms give

$$N_{ik} = \frac{(1 - \alpha_k)}{\alpha_k} \frac{r_{ik} L_{ik}}{w_i}.$$
(A5)

Third, the optimal allocation of landowners gives

$$L_{ik} = \frac{r_{ik}^{\theta}}{r_{iA}^{\theta} + r_{iM}^{\theta}}L.$$
(A6)

Fourth, workers are fully employed

$$N = \sum_{i} \sum_{k} N_{ik}.$$
 (A7)

Fifth, workers are indifferent between Village and Town

$$\frac{w_V}{p_V} = \frac{w_T}{p_T},\tag{A8}$$

where $p_i = p_{iA}^{\mu_A} p_{iM}^{\mu_M}$ is the consumer price index. Using equations (A3) to (A8), we can solve for the endogenous variables of the model.

Numerical Example. Figure A1 shows a numerical example of the model developed above for parameter values $\{\theta, \gamma, \alpha_A, \alpha_M, \mu_k, \tau\} = \{2, 0.1, 0.5, 0.2, 0.5, 1.05\}$, agricultural productivities $A_{FA} = A_{TA} = A_{VA} = 1$, initial conditions for manufacturing productivities $A_{FM0} = A_{TM0} =$ 1 and $A_{VM0} = 0.8$, land endowment $L_V = L_T = 0.5$, population $N_H = N_F = 1$. These parameters ensure full specialization of Village in any period of time. We illustrate the impact of an agricultural productivity shock by increasing A_{iA} by 10%.

Appendix Figure A1.1 shows that the agricultural productivity shock has a permanent negative effect on the population in Town. With the agricultural productivity shock, the manufacturing sector shrinks, and the region gains comparative advantage in agriculture, which has no productivity growth over time. That puts Town in a path of permanent lower economic growth and smaller incentives for the inflow of workers. In Village, on the other hand, the opposite happens. The agricultural productivity shock holds the outflow of workers and puts the economy on a path with larger population. This happens, in part, because of the general equilibrium effects in Town: with more workers in Village, there are fewer workers in Town, the price of land in Town drops, which makes Town specialize in agriculture and enter in a path of lower economic growth.

A1.3: Share of Agricultural Land

Notes: These figures show a numerical example of the impact of an agricultural productivity shock in a village versus a town using our stylized spatial economy model. In black dashed line we have the path for villages (for an agricultural productivity shock in villages) and in red line the path for towns (for an agricultural productivity shock in towns). It shows that the shock has a positive effect on population in village, but a negative in town. In addition, the figure shows that the shock, in both cases, has a positive effect on the share of labor and land in agriculture, but the effect tends to be larger in towns.

Figure A1.2 and Figure A1.3 show the effect on agricultural employment and land. In Town, the productivity shock generates a permanent effect on the share of workers and land in agriculture. This gap widens over time. In Village, on the other hand, the productivity shock generates an initial expansion, but the effect of the initial shock is attenuated over time since the region becomes fully specialized in agriculture both in the couterfactual and the factual scenario. In the case of Village, the productivity shock basically anticipates the specialization of the region in agriculture. These numerical examples suggest that the impact on the share of employment in agriculture should be smaller in Village (relative to Town), which is indeed something that we observe in the data.

As expected, the impact of the agricultural productivity depends on initial conditions. If, for example, $A_{FM0} = A_{TM0} = A_{VM0} = 1$ and $A_{FA} = A_{TA} = A_{VA} = 1$, then all regions have the same comparative advantage. Since there are no incentives for trade in this case, all regions have the same relative price of agricultural goods and keep a constant share of workers in manufacturing and total population in the absence of the shock. Here, an agricultural productivity shock has a negative effect on total population both in Village and in Town. Interestingly, if $A_{FM0} = A_{TM0} = A_{VM0} = 1$ and $A_{FA} = A_{TA} = 1$ and $A_{VA} = 0.9$, then Town and Village have a larger share of workers in manufacturing in the initial period relative to the rest of the world ($n_{VM0} > n_{FM}^*$ and $n_{TM0} > n_{FM}^*$). Relative to the ROW, Town specializes in manufacturing because of its larger population density and Village specializes in manufacturing because of its relative productivities. In that case, a positive productivity shock in agriculture generates a negative effect on the evolution of total population both in Town and in Village.

A2 Appendix: Data and Background

Census of India. The Census of India is a population-wide enumeration exercise conducted in the country every ten years. It publishes data on demographics, economic activity, educational attainment, migration, fertility and household amenities and assets for the entire country, aggregated at the village and town level. We use three 'series' of the census in this paper: (i) A-Series: General Population; (ii) B-Series: Economic Tables; (iii) H-Series: Houses, Household Amenities and Assets Tables.

From the A-Series, we extract data on total population in a village/town, population of Scheduled Castes (SCs) and population of Scheduled Tribes (STs).¹⁸ From the B-Series, we use data to

¹⁸SCs and STs are the most marginalized communities in the country.
classify workers as those engaged in agricultural or non-agricultural practices. The census distinguishes between workers according to: (a) whether workers worked more than half of the months in a year viz. 'main' (\geq 6 months) and 'marginal' (< 6 months) workers; (b) type of work which is categorized in 4 ways viz cultivators, agricultural laborers, household industry workers and others; and (c) sector of employment which is categorized in 9 ways viz. agricultural and allied activities, mining and quarrying, manufacturing, electricity, gas and water supply, construction, wholesale, retail trade and repair work, hotel and restaurants, transport, storage and communications, financial intermediation, real estate, business activities, and other services.

In 2011, there were 481.7 million workers in the country, out of which 118.7 million were cultivators, 144.3 million agricultural laborers, 18.3 million household industry workers and 200.4 million other types of workers. Cultivators are defined as those who are directly engaged in farming or involved in the supervision of farm activities.¹⁹ Agricultural laborers are those who worked someone else's land in exchange for wages either in cash or kind. Household industry workers refer to those who are involved in the production, processing, servicing, repairing or making and selling of goods, as long as the 'industry' involved members of household and run on a small scale and not that of a factory.

Overall, there are 362 million 'main' workers and 119 million 'marginal' according to the Census of India 2011.

Economic Census. The economic census is a complete enumeration of non-agricultural enterprises in India. While recent economic censuses have expanded the scope to cover establishments engaged in various agricultural activities, the strength of the economic census lies in providing firm-level information on employment for non-agricultural establishment.²⁰ In 2012-13 there were approx. 45 million non-agricultural enterprises, employing 108 million workers in the country. An advantage of the economic census is that it allows us to explore heterogeneous impacts on firms by their size and disaggregate the specific sub-sectors which is not possible in

¹⁹Farming is defined as ploughing, sowing and harvesting cereals, millets, pulses or fibre crops. The cultivation of fruits, vegetables, growing orchards/groves or working on plantations is not included as farm activities.

²⁰Public administration, defence and social security activities are excluded

the Census of India.

Irrigation. Dams, especially embankment dams, are an an important source of irrigation in India. The mean (median) number of dams in an Indian district has increased from 2.05 (0) to 7.84 (1) in the period 1970 to 1999. Although there has been a significant rise in the number of dams over the years, their distribution is not uniform across states. Instead, the new dams have been primarily concentrated in the western region, especially Maharashtra and Gujrat (Duflo and Pande, 2007).

Embankment dams are built using an artificial wall dividing the area into *catchment* and *command* areas. *Catchment* area refers to upstream part of the dam from which the water flows in, whereas *command* areas refers to the downstream part from where the water is then channelled for irrigation through a network of canals. By design, the benefits of these dams for irrigation purposes are limited to those who live in the *command* area.

In India, constructing a dam requires approval both by state and national governments, and is thus subject to a proper cost benefit analysis (Asmal et al., 2000). Although the benefit is often measured in terms of agricultural output and the value of power to be generated, the costs are much more complicated to evaluate (Duflo and Pande, 2007). Geography is an important determinant of the cost: for example, a river that flows at a moderate incline makes it easier and cheaper to construct a dam. Additional hidden costs includes dam's impact on land productivity due to water-logging and water salinity, and the concomitant impacts on the health of those living in nearby areas, and displacement of the people to name a few.

This form of irrigation using canals connected to dams is the most important form of irrigation in India because it is cheaper than other alternatives. Ground water and small dykes are two potential alternatives. In contrast to dams, these alternative are less effective, especially in areas like India with high seasonal rainfall (Biswas and Tortajada, 2001).

Towns. An important element of our analysis is the differential effects of being in a command area on villages and towns. It is therefore important to clearly articulate the administrative,

demographic, and economic characteristics that distinguish towns from villages.

Administratively, towns differ from villages due to their being governed by municipal corporations, and municipality and city councils. In contrast, most village-level administration is undertaken by larger administrative units, such as sub-district and district authorities, though some functions are reserved to village governing bodies (i.e., panchayats). This administrative distinction has one notable exception, however: specifically, the "census towns," which are classified by the Registrar General of India as being towns due to their population size, density, and labor force composition,²¹ but which have not yet been granted official statutory township status by the government (Pradhan, 2017). Despite lacking urban governing institutions, census towns display similar levels of prosperity and economic diversification as statutory towns, and differ markedly from the typical village. We, therefore, refer to all the non-village sites as "towns."

Demographically, towns have far larger populations than villages, and a far higher population density. Economically, towns differ from villages by the share of agricultural in local employment and production. Though towns may include significant agricultural activities, and to employ a substantial share of the land within their boundaries to agriculture, the scale of these activities is vastly smaller. In addition, towns feature a far larger number of firms engaged in manufacturing and other non-agricultural activities, which are more likely to be formalized, and operate on a far larger scale. Towns also feature substantial retail, wholesale, and transport sectors: indeed, one of the major drivers of the recent growth of towns in rural areas has been their role as markets and distribution centers for nearby villages.

Appendix Table A2 depicts some of the key differences between villages and towns. In column (1) of Panel B are given the mean characteristics of villages in the study area. In column (2) we present the difference between towns and villages; in column (3) we include project-area fixed effects; and in column (4) we restrict the sample of towns to those occupying less than 30 square kilometers. This table highlights the starkly different character of towns and villages, with the latter having more built-up area and less agricultural, more light density, higher population and

²¹Census towns must meet three criteria: (1) a population greater than 5000; (2) a population density above 400 individuals per square kilometer; and (3) a male labor force which is less than 25% engaged in agriculture.

population density, and greater asset holdings and household amenities. Towns also feature less agricultural employment, and more employment in service and manufacturing firms, of which a larger share is in large firms with more than 10 or 100 workers.

In Appendix Figure A2 we show the relationship between distance to nearest town and the structure of the economy (with towns taking a distance value of 0), again illustrating both the differences between villages and towns, and the somewhat more "urban" economic structure of those villages located in the immediate vicinity of towns.

Town Formation. One potential concern with our analysis is that whether a village graduates to the status of being a town is itself endogenous. This could lead to the result that a village experiencing a large increase in population could be reclassified as a town with a small population. In Appendix Table A1 we test for endogenous town formation.

According to the Census of India, a 'census town' is defined as one where the population exceeds 5,000, population density is more than 400 persons per sq km, and more than 75 percent of main male working population is employed outside the agricultural sector. We therefore define a 'marginal sample' as villages and towns that were close to meeting the criterion i.e. a population between 4000 and 6000 people, a population density of more than 350 persons per km sq, and male labor force greater than 70 percent that is engaged in non-agricultural production.

In Appendix Table A1, column (1), we restrict the sample to villages and towns that were close to meeting the criterion for township formation (the 'marginal sample') and estimate the impact of being in the program areas on attaining township status. In columns (2) and (3), we restrict the sample to all towns, and take as the outcome variable an indicator for whether the town already had township status in 1951 and 1971, respectively. In columns (4)–(5), we take as the outcome the log *area* within towns, where land within villages take a value of 0, and towns take the natural log of their areas.

We find no impact on whether villages are graduated to township status, nor on how early existing towns were formed. In addition, we find no impact on the total area of the command area that is within a township (column 4), or on the size of towns (column 5). Essentially, this means that the 6.3% increase in village population in treatment areas (coupled with changes in the labor share in agriculture) was insufficiently large to graduate villages to township status. This is intuitive, given the dramatically larger populations of towns, and their far smaller agricultural labor shares. The area covered by towns was no different in control and treatment areas: towns were simply less populated and built-up in the latter.

		Existin	g Town	Log	Гown

Village Sample	Yes			Yes	
Marginal Sample	Yes				

Table A1: Town Formation

Note: In column (1), the outcome variable is an indicator for township status; and the sample is restricted to villages and towns that have a population between 4000–6000, a male labor force share <0.30 in agriculture, and a population density greater than 350 per square km. In columns (2) and (3), the outcome variable is an indicator for having been a township in 1951 and 1971, respectively. Columns (4) and (5) take as the outcome the log area of towns, which takes a value of 0 for villages.

A3 Appendix: Additional Figures and Tables

Figure A2: Spatial Distribution of Economic Activity

A2.3: Firm Size

Notes: The above figure plots the spatial distribution of economic activity of villages relative to towns. Distance from village centroid to the nearest town (in km) is on the x-axis. Figure A2.1 depicts the population density per 1,000 square km (Census of India 2011) on the left y-axis and percentage of built-up area on the right y-axis. Figure A2.2 depicts percent of workers in agriculture (Census of India 2011), manufacturing and service sectors (Economic Census 2012-13). Figure A2.3 depicts employment by firm size (Economic Census 2012-13).

Figure A4: Agriculture by Boundary Type

A4.3: Dry Season Vegetation

Notes: The above figure compares key agricultural outcomes in villages inside the command area (to the left of 0) with those just outside (to the right of 0). Distance from village centroid to the command area (in km) is on the x-axis. The solid line represents results from a regression of outcomes on canal command area treatment dummy, binned distances, controls and 5 km boundary segment fixed effects. Standard errors are clustered at the project code level. The dotted lines represent 95% confidence intervals. The black lines refers to the sample which only had a contiguous canal and command area boundary, while the blue lines refers to the non-canal boundary (see definitions in text). Figure A4.1 depicts area under irrigation in percent of cultivable land (Census of India 2011), Figure A4.2 depicts land area that is cropped twice or thrice in percent of agricultural area (NRSC/ISRO 2011-12), and Figure A4.3 depicts dry season vegetation indices in percent of total village area (MODIS EVI 20013).

Figure A5: Agriculture and Development, w/o Geographic Controls

A5.6: Log Firm Employment

Notes: The above figure compares key agricultural and development outcomes in villages inside the command area (to the left of 0) with those just outside (to the right of 0). Distance to the command area (in km) is on the x-axis. The solid line represents results from a regression of outcomes on canal command area treatment dummy, binned distances, controls and 5 km boundary segment fixed effects. Standard errors are clustered at the project code level. The dotted lines represent 95% confidence intervals. Figure A5.1 depicts area under irrigation as percent of cultivable land; Figure A5.2 depicts land area that is cropped twice or thrice as percentage of agricultural area; and Figure A5.3 depicts dry season vegetation indices as percentage of total village area. Figure A5.4 depicts log population density; Figure A5.5 depicts mean nighttime lights per sq km; Figure A5.6 depicts number of employees in firms across manufacturing, agriculture and services enterprises.

Figure A6: Robustness to varying bandwidths

A6.1: Villages

A6.2: Towns

Notes: The figures plot the impact on key agricultural and non-agricultural outcomes for villages and towns using alternative bandwidths (2 km, 5 km, 10 km, 15 km, 20 km, 25 km and 30 km). Capped spike intervals report the 90 percent while the longer intervals report the 95 percent confidence intervals. Agricultural outcomes are derived from satellite data. Cultivated area refers to percentage of area cultivated; multi-season cropping refers to area cropped twice or thrice in a year; and dry-season vegetation refer to MODIS EVI 2013. The non-agricultural outcomes are: population density; night light density; and built-up area. 46

Table A3: Balance, Geographic Features

Notes: Table reports results from equation: $y_{idb} = \alpha + \beta C_i + \nu_d + \mu_b + \varepsilon_{idb}$ where, y_{idb} is an outcome of interest in village i in district d in a 10 km buffer around boundary segments b; C_i is an indicator variable indicating whether the centroid of a village is located inside command area or not; ν_d are district fixed effects; and μ_b are 5 km boundary segment fixed effects. The outcomes are altitude (in meters), terrain ruggedness index derived from USGS digital elevation models, distance to river (in kms), and whether a village lies on top of an alluvium/water-deposited aquifer. Standardized z-scores for the outcomes are in square brackets. Column 1 reports the mean of the outcome outside the command area; Column 2 reports the difference between villages inside and outside the command area in the full sample; Column 3 and Column 4 refer to the trimmed sample. (In the trimmed sample, the sample is restricted to villages for which the average slope on both sides is less than 1.5 degrees; boundaries where the canal is within 500m of a river are also excluded.) Column 3 uses the baseline specification mentioned above; Column 4 additionally includes treatment-interacted control for distance to the command area boundary. Standard errors are clustered by command area (irrigation project) to conservatively account for potential spatial correlation. * p<0.10, ** p<0.05, *** p<0.01.

Notes: Table reports results from two estimating equations: $y_{ipdb} = \alpha + \beta C_i + \mathbf{X}_i \Gamma + \nu_d + \eta_p + \varepsilon_i$ (columns 1 and 3) and $y_{ipdb} = \alpha + \beta C_i + \mathbf{X}_i \Gamma + \nu_d + \mu_b + \varepsilon_i$ (columns 2 and 4) where, y_{ipdb} is an outcome of interest in location *i* (village or town) in a 10 km buffer around irrigation project *p* in district *d* along boundary segment *b*; C_i is an indicator variable for whether the centroid of a location lies inside a command area of project *p* or not; X_i is a vector of geographic characteristics like altitude, ruggedness, distance to major river, type of groundwater aquifer underlying the location, the (log) area of the location; ν_d are district fixed effects; η_p are project fixed effects; and μ_b are 5 km boundary segment fixed effects. Estimating sample is restricted to locations for which the average slope on both sides of the boundary is less than 1.5 degrees and to location swith area less than 30 sq. km; boundaries where the canal is within 500m of a river are also excluded. The outcomes are derived from census and satellite data: panel A reports ln(population density) from Census of India 2011; panel B reports ln(mean nighttime luminosity score per sq km) from NOAA 2013; and panel C reports ln(built up area) from NRSC/ISRO 2011-12. Standard errors are clustered by command area (irrigation project) to conservatively account for potential spatial correlation. * p<0.10, ** p<0.05, *** p<0.01.

Table A8 – Continued fror	n previous page	e		
R-squared	0.471	0.550	0.525	0.636
N	128402	125796	1467	781
Project FE	Yes		Yes	
Boundary Segment FE		Yes		Yes
District FE	Yes	Yes	Yes	Yes

Notes: Table reports results from two estimating equations: $y_{ipdb} = \alpha + \beta C_i + \mathbf{X}_i \Gamma + \nu_d + \eta_p + \varepsilon_i$ (columns 1 and 3) and $y_{ipdb} = \alpha + \beta C_i + \mathbf{X}_i \Gamma + \nu_d + \mu_b + \varepsilon_i$ (columns 2 and 4) where, y_{ipdb} is an outcome of interest in location i (village or town) in a 10 km buffer around irrigation project p in district d along boundary segment b; C_i is an indicator variable for whether the centroid of a location lies inside a command area of project p or not; X_i is a vector of geographic characteristics like altitude, ruggedness, distance to major river, type of groundwater aquifer underlying the location, the (log) area of the location; ν_d are district fixed effects; η_p are project fixed effects; and μ_b are 5 km boundary segment fixed effects. Estimating sample is restricted to locations for which the average slope on both sides of the boundary is less than 1.5 degrees and to locations with area less than 30 sq. km; boundaries where the canal is within 500m of a river are also excluded. The outcomes are derived from Economic Census 2012-13: panel A reports ln(total employment) in all enterprises/firms. Total employment = agriculture + manufacturing + services. Panel B reports ln(manufacturing sector employment); panel C reports ln(agricultural sector employment); panel D reports ln(service sector employment). While panel B to panel D report sectoral impacts, panel E to panel H report impacts by firm size: panel E, F, G and H report ln(employment) for firms with greater than 100 workers, between 50-99 workers, 10-49 workers and less than 10 workers respectively. Standard errors are clustered by command area (irrigation project) to conservatively account for potential spatial correlation. * p<0.10, ** p<0.05, *** p<0.01.
